

Obsidian

A Safer Blockchain Programming Language

What is a blockchain?

- Blockchain programming environments provide *shared, global state on untrusted, distributed computing nodes*.
- Global state consists of *smart contracts*, which include both data structures and *transactions* that manipulate them.
- Transactions can *deploy* smart contracts to the blockchain (initializing their state), or *invoke* code implemented in specific deployed smart contracts.
- “Code is law”: a principle that suggests that a contract’s code specifies an agreement between parties. This principle implies that contracts are *immutable*; bugs in them cannot be fixed after deployment.

One blockchain network node

A 3-block blockchain

Key-value store with state of all contracts

The nodes execute a *consensus protocol* by which they agree on which transactions have been processed and in what order. After consensus is reached, all nodes agree on the transactions and their ordering.

Blockchain facts	Consequences	Design approach
Smart contracts can hold resources .	Bugs can transfer resources to the wrong party or lose them entirely. A bug was recently exploited to steal over US\$40M from a contract.	Obsidian models resources with linear types , which statically restrict lifecycles, so that resources cannot be accidentally lost.
Modifying a contract’s code could change an agreement that parties have settled on.	Smart contracts are immutable once deployed, but this means that bugs are not fixable.	Support developer-authored specifications and use verification tools to prove that the code satisfies the specifications. Use a strong, static type system to detect as many bugs as possible at compile time.
Proposed application domains, such as finance and medical records, cannot tolerate serious bugs.	Correct software is paramount.	
Many proposed applications are inherently <i>stateful</i> .	Blockchain applications commonly implement state machines . Behavior and available transactions depend on the current state.	Obsidian is a typestate-oriented language , representing <i>state</i> in <i>types</i> and statically preventing some invalid invocations. For example, a Bond that has been bought is in the Bought state and cannot be bought again.

Annotated example code

```
interface account { transaction pay (money m); }
resource contract money {...}; ← Instances of resource contracts,
contract Bond {                                     ← unlike other contracts, always have
  account seller;                                  ← exactly one owning reference.
  Bond(account s) {
    seller = s;
    -> Offered(); ← The constructor transitions to
  }                                                  ← Offered state at the end.
  state Offered {
    transaction buy(money m, account b) {
      seller.pay(m); ← After this line, the transaction no longer owns m.
      -> Sold({buyer = b}); ← Transition to Sold state with buyer
    }                                               ← field set to b.
  }
  state Sold {
    account buyer;
    transaction makePayment(money m) {
      buyer.pay(m);
    }
  }
}
contract ErroneousClient {
  transaction badTransaction() {
    Bond.Offered b = new Bond(...);
    b.buy(...); ← Type of b after this line is Bond.Sold due to buy() invocation.
    b.buy(...); ← Compile error: b is of type Bond.Sold, which has no
  }                                               ← buy() transaction.
}
}
```

Status and Upcoming Work

- An initial compiler translates Obsidian code to Java (for execution on a mock blockchain) and to Dafny (for verification).
- The compiler includes a typechecker based on a draft typesystem.
- We plan to port Obsidian to Hyperledger Fabric and complete the compiler.
- Our evaluation will ask users to write programs in Obsidian and either Hyperledger Composer or Solidity (existing blockchain development tools) and compare task completion times and rates and kinds of bugs.
- We are iteratively evaluating portions of the language design in the context of Java so that we can isolate those parts of the design for study.
